Min-Cost Multiflows in
Node-Capacitated Undirected Networks

Maxim A. Babenko * Alexander V. Karzanov †

February 2, 2011

Abstract

We consider an undirected graph \( G = (VG, EG) \) with a set \( T \subseteq VG \) of terminals, and with nonnegative integer capacities \( c(v) \) and costs \( a(v) \) of nodes \( v \in VG \). A path in \( G \) is a \( T \)-path if its ends are distinct terminals. By a multflow we mean a function \( F \) assigning to each \( T \)-path \( P \) a nonnegative rational weight \( F(P) \), and a multflow is called feasible if the sum of weights of \( T \)-paths through each node \( v \) does not exceed \( c(v) \). The value of \( F \) is the sum of weights \( F(P) \), and the cost of \( F \) is the sum of \( F(P) \) times the cost of \( P \) w.r.t. \( a \), over all \( T \)-paths \( P \).

Generalizing known results on edge-capacitated multiflows, we show that the problem of finding a minimum cost multflow among the feasible multiflows of maximum possible value admits half-integer optimal primal and dual solutions. Moreover, we devise a strongly polynomial algorithm for finding such optimal solutions.

Keywords: minimum cost multflow, bidirected graph, skew-symmetric graph

1 Introduction

1.1 Multiflows

For a function $\varphi : X \to \mathbb{R}_+$ and a subset $A \subseteq X$, we write $\varphi(A)$ to denote $\sum_{x \in A} \varphi(x)$. The incidence vector of $A$ in $\mathbb{R}^X$ is denoted by $\chi^A$, i.e., $\chi^A(e) = 1$ for $e \in A$ and 0 for $e \in X - A$ (usually $X$ will be clear from the context). When $A$ is a multiset, $\chi^A(e)$ denotes the number of occurrences of $e$ in $A$.

In an undirected graph $G$, the sets of nodes and edges are denoted by $VG$ and $EG$, respectively. When $G$ is a directed graph, we speak of arcs rather than edges and write $AG$ instead of $EG$. A similar notation is used for paths, cycles, and etc.

A walk in $G$ is meant to be a sequence $(v_0, e_1, v_1, \ldots, e_k, v_k)$, where each $e_i$ is an edge (or arc) and $v_{i-1}, v_i$ are its endnodes; when $G$ is a digraph, $e_i$ is directed from $v_{i-1}$ to $v_i$. Edge-simple (or arc-simple) walks are called paths.

We consider an undirected graph $G$ and a distinguished subset $T \subseteq VG$ of nodes, called terminals. Nodes in $VG - T$ are called inner. A $T$-path is a path $P$ in $G$ whose endnodes are distinct terminals; we usually assume that all the other nodes of $P$ are inner. The set of $T$-paths is denoted by $\mathcal{P}$. A multflow is a function $F : \mathcal{P} \to \mathbb{Q}_+$. Equivalently, one may think of $F$ as a collection

\[(1.1) \quad \{(\alpha_1, P_1), \ldots, (\alpha_n, P_n)\}
\]

(for some $m$), where the $P_i$ are $T$-paths and the $\alpha_i$ are nonnegative rationals, called weights of paths. Sometimes (e.g., in [IKN98]) such a multflow $F$ is called free to emphasize that all pairs of distinct terminals are allowed to be connected by flows. The value val($F$) of $F$ is $\sum_{P} F(P)$. For a node $v$, define

\[(1.2) \quad \hat{F}(v) := \sum_{P \in \mathcal{P}, v \in V P} F(P) ;
\]

the function $\hat{F}$ on $VG$ is called the (node) load function. Let $c : VG \to \mathbb{Z}_+$ be a nonnegative integer function of node capacities. We say that $F$ is feasible if $\hat{F}(v) \leq c(v)$ for all $v \in VG$.

Suppose we are given, in addition, a function $a : VG \to \mathbb{Z}_+$ of node costs. Then the cost $a(F)$ of a multflow $F$ is the sum $\sum_{P} a(P)F(P)$, where $a(P)$ stands for the cost $a(VP)$ of a path $P$.

In this paper we consider the following problem:

\[ (N) \quad \text{Given } G, T, c, a \text{ as above, find a multflow } F \text{ of minimum possible cost } a(F) \text{ among all feasible multiflows of maximum possible value.} \]

1.2 Previous results

When $|T| = 2$, $(N)$ turns into the undirected min-cost max-flow problem under node capacities and costs, having a variety of applications; see, e.g., [FF62, La76]. It admits integer optimal primal and dual solutions [FF62].

In the special case $a \equiv 0$, we are looking simply for a feasible multflow of maximum value. Such a problem has half-integer optimal primal and dual solutions, due to results
of Pap [Pa07] and Vazirani [Va01], respectively. Also it is shown in [Pa07] that the problem is solvable in strongly polynomial time by using the ellipsoid method.

An edge-capacitated version of (N) has been well studied. In this version, denoted by (E), c and a are functions on EG rather than VG. For a multflow F, its edge load function is defined similarly to (1.2):

\( \tilde{F}(e) := \sum (F(P) : P \in \mathcal{P}, e \in EP) \) for all \( e \in EG, \)

and its cost is defined to be \( \sum_P a(EP)F(P) \). Problem (E) is reduced to (N) by adding an auxiliary node on each edge, but no converse reduction is known.

An old result is that (E) has a half-integer optimal solution [Ka79]. Also it is shown in [Ka94] that (E) has a half-integer optimal dual solution and that half-integer primal and dual optimal solutions can be found in strongly polynomial time by using the ellipsoid method. A “purely combinatorial” weakly polynomial algorithm, based on cost and capacity scaling, is devised in [GK97].

In the special case of (E) with \( a \equiv 0 \), the half-integrality results are due to Lovász [Lo76] and Cherkassky [Ch77], and a strongly polynomial combinatorial algorithm is given in [Ch77] (see also [IK08] for faster algorithms).

### 1.3 New results

In this paper we prove that (N) always admits half-integer optimal primal and dual solutions. In particular, this implies all half-integrality results mentioned in the previous subsection.

Similar to [Ka94], we introduce a parametric generalization of (N), study properties of geodesics (shortest \( T \)-paths with respect to some length function), and reduce the parametric problem to a certain single-commodity flow problem. However, the details of this construction are more involved. In particular, the reduced problem concerns integer flows in a bidirected graph.

The second goal is to explore the complexity of (N). We show that half-integer optimal primal and dual solutions to the parametric problem (and therefore to (N)) can be found in strongly polynomial time by using the ellipsoid method.

### 2 Preliminaries

#### 2.1 Parametric problem and its dual

Instead of (N), it is convenient to consider a more general problem, namely:

\((N_\lambda)\) Given \( G,T,c,a \) as in (N) and, in addition, \( \lambda \in \mathbb{Z}_+ \), find a feasible multflow \( F \) maximizing the objective function \( \Phi(F,a,\lambda) := \lambda \cdot \text{val}(F) - a(F) \).

We will prove the following

**Theorem 2.1** For any \( \lambda \in \mathbb{Z}_+ \), problem \((N_\lambda)\) has a half-integer optimal solution.

(Note that \( \Phi(F,qa,q\lambda) = q \cdot \Phi(F,a,\lambda) \) for any multflow \( F \) and \( q \in \mathbb{Q}_+ \). Therefore, the optimality of a multflow in the parametric problem preserves when both \( a \) and \( \lambda \) are...
multiplied by the same positive factor $q$. This implies that the theorem is generalized to arbitrary $a : VG \to \mathbb{Q}_+$ and $\lambda \in \mathbb{Q}_+$ (but keeping the integrality of $c$). However, we prefer to deal with integer-valued $a$ and $\lambda$ in what follows.

By standard linear programming arguments, $(N)$ and $(N_\lambda)$ become equivalent when $\lambda$ is large enough (moreover, the existence of a half-integer optimal solution for $(N_\lambda)$ easily implies that taking $\lambda := 2c(VG)a(VG) + 1$ is sufficient).

Problem $(N_\lambda)$ can be viewed as a linear program with variables $F(P) \in \mathbb{Q}_+$ assigned to $T$-paths $P$. Assign to a node $v \in VG$ a variable $l(v) \in \mathbb{Q}_+$. Then the linear program dual to $(N_\lambda)$ is:

\[(D_\lambda) \text{ Minimize } c \cdot l \text{ provided that the following holds for every } T\text{-path } P: \]
\[l(P) \geq \lambda - a(P). \]

### 2.2 Translating to edge lengths

The above dual problem $(D_\lambda)$ involves lengths of paths (namely, $l(P)$ and $a(P)$) determined by “lengths” of nodes ($l$ and $a$, respectively). It is useful to transform lengths of nodes into lengths of edges. To do so, for $w : VG \to \mathbb{Q}_+$, we define the function $\overline{w}$ on $EG$ by
\[
(2.2) \quad \overline{w}(e) := \alpha_u w(u) + \alpha_v w(v) \quad \text{ for } e = uv \in EG,
\]
where $\alpha_x := \frac{1}{2}$ if $x \in VG - T$, and $\alpha_x := 1$ if $x \in T$. This provides the correspondence
\[
(2.3) \quad w(P) = \overline{w}(P) \quad \text{ for each } T\text{-path } P
\]
(where $w(P)$ stands for $w(VP)$, and $\overline{w}(P)$ for $\overline{w}(EP)$). For $a, l$ as above, define
\[
(2.4) \quad \ell := \overline{l} + \overline{\lambda}.
\]

Let $\text{dist}_\ell(u, v)$ denote the $\ell$-distance between vertices $u$ and $v$, i.e. the minimum $\ell$-length $\ell(P)$ of a $u$-$v$ path $P$ in $G$. Then, in view of (2.3) and (2.4), the constraints in $(D_\lambda)$ can be rewritten as
\[
(2.5) \quad \text{dist}_\ell(s, t) \geq \lambda \quad \text{ for all } s, t \in T, s \neq t.
\]

By the linear programming duality theorem applied to $(N_\lambda)$ and $(D_\lambda)$, a feasible multiflow $F$ and a function $l : VG \to \mathbb{Q}_+$ satisfying (2.5) are optimal solutions to $(N_\lambda)$ and $(D_\lambda)$, respectively, if and only if the following (complementary slackness conditions) hold:
\[
(2.6) \quad \text{if } P \text{ is a } T\text{-path and } F(P) > 0, \text{ then } \ell(P) = \lambda; \text{ in particular, } P \text{ is } \ell\text{-shortest};
\]
\[
(2.7) \quad \text{if } v \in VG \text{ and } l(v) > 0, \text{ then } v \text{ is saturated by } F, \text{ i.e. } \overline{F}(v) = c(v).
\]

In the rest of the paper, to simplify technical details, we will always assume that the input costs $a$ of all nodes are strictly positive. Then the edge lengths $\ell$ defined by (2.4) are strictly positive as well. This assumption will not lead to loss of generality in essence, since the desired results for a nonnegative input cost function $a$ can be obtained by applying a perturbation technique in spirit of [Ka94, pp. 320–321] (by replacing $a$ by an appropriate strictly positive cost function).
2.3 Geodesics

Condition (2.6) motivates the study of the structure of $\ell$-shortest $T$-paths in $G$. To this aim, set $p := \min\{\text{dist}_\ell(s, t) \mid s, t \in T, s \neq t\}$. A $T$-path $P$ such that $\ell(P) = p$ is called an $\ell$-geodesic (or just geodesic if $\ell$ is clear from the context). When a multilow $F$ in $G$ is given as a collection (1.1) in which all paths $P_i$ are $\ell$-geodesics, we say that $F$ is an $\ell$-geodesic multilow.

Next we utilize one construction from [Ka79, Ka94], with minor changes. Consider a node $v \in VG$. Define the potential $\pi(v)$ to be the $\ell$-distance from $v$ to the nearest terminal, i.e. $\pi(v) := \min\{\text{dist}_\ell(v, t) \mid t \in T\}$. Set $VG_\ell := \{v \in VG \mid \pi(v) \leq \frac{1}{2}p\}$ (in particular, $T \subseteq VG_\ell$). For $s \in T$, define $V^s := \{v \in VG \mid \text{dist}_\ell(s, v) < \frac{1}{2}p\}$. Also define $V^2 := \{v \in VG \mid \pi(v) = \frac{1}{2}p\}$. We refer to $V^s$ as the zone of a terminal $s \in T$, and to $V^2$ as the set of central nodes (w.r.t. $\ell$). The sets $V^s$ ($s \in T$) and $V^2$ are pairwise disjoint and give a partition of $VG_\ell$.

The following subset of edges is of importance:

\[ E_G := \{uv \in EG \mid \exists s \in T : u \in V^s, v \in V^t, |\pi(u) - \pi(v)| = \ell(uv)\} \]
\[ \cup\{uv \in EG \mid \exists s, t \in T, s \neq t : u \in V^s, v \in V^t, \pi(u) + \pi(v) + \ell(uv) = p\}. \]

One can see that the subgraph $G_\ell := (VG_\ell, E_G)$ of $G$ contains all $\ell$-geodesics. Moreover, a straightforward examination shows that the structure of $\ell$-geodesics possess the properties as expressed in the following lemma (which is, in fact, a summary of Claims 1–3 from [Ka94] and uses the strict positivity of $\ell$).

**Lemma 2.2** Let $P$ be an $\ell$-geodesic running from $s \in T$ to $t \in T$. Then $P$ is contained in $G_\ell$ and exactly one of the following takes place:

1. $P$ contains no central nodes and can be represented as the concatenation $P_1 \circ (u, e, v) \circ P_2$, where $u \in V^s$, $v \in V^t$, $s \neq t$, and $e \in E_G$.
2. $P$ contains exactly one central node $w \in V^2$ and can be represented as the concatenation $P = P_1 \circ (u, e_1, w, e_2, v) \circ P_2$, where $u \in V^s$, $v \in V^t$, $s \neq t$, and $e_1, e_2 \in E_G$.

In both cases, parts $P_1$ and $P_2$ are contained in the induced subgraphs $G_\ell[V^s]$ and $G_\ell[V^t]$, respectively. The potentials $\pi$ are strictly increasing as we traverse $P_1$ from $s$ to $u$, and strictly decreasing as we traverse $P_2$ from $v$ to $t$.

Conversely, any $T$-path in $G_\ell$ obeying the above properties is an $\ell$-geodesic.

3 Primal half-integrality

3.1 Auxiliary bidirected graph

In this subsection we introduce an auxiliary bidirected graph, which will be the cornerstone of our approach both for proving half-integrality results and for providing a polynomial-time algorithm.

Given $G, T, c, a$ and $\lambda$ as above, let $l$ be an optimal solution to $(D_\lambda)$. Form the edge lengths $\ell := \overline{l} + \pi$, the potential $\pi$, the subgraph $G_\ell$, and the sets $V^s$ ($s \in T$) and $V^2$, as in Subsection 2.3. One may assume that $p := \min\{\text{dist}_\ell(s, t) \mid s, t \in T, s \neq t\} = \lambda$ (since $p \geq \lambda$, by (2.5), and if $p > \lambda$ then $F = 0$ is an optimal solution to $(N_\lambda)$, by (2.6)).
For further needs, we reset $c := 2c$, making all node capacities even integers. Now our goal is to prove the existence of an integer optimal multflow $F$ in problem $(N_3)$ (which is equivalent to proving the half-integrality w.r.t. the initial $c$).

Recall that in a bidirected graph (or a BD-graph for short) edges of three types are allowed: a usual directed edge, or an arc, that leaves one node and enters another one; an edge directed from both of its ends; and an edge directed to both of its ends (cf. [EJ70, Sc03]). When both ends of an edge coincide, the edge becomes a loop. For our purposes we admit no loop entering and leaving its end node simultaneously. Sometimes, to specify the direction of an edge $e = uv$ at one or both of its ends, we will draw arrows above the corresponding node characters. For example, we may write $\overrightarrow{u} \overrightarrow{v}$ if $e$ is directed from $u$ to $v$ (a usual arc), $\overrightarrow{u} \overleftarrow{v}$ if $e$ leaves both $u, v$, and $\overleftarrow{u} \overrightarrow{v}$ if $e$ leaves $u$ (and either leaves or enters $v$).

A walk in a BD-graph is an alternating sequence

$$P = (s = v_0, e_1, v_1, \ldots, e_k, v_k = t)$$

of nodes and edges such that each edge $e_i$ connects nodes $v_{i-1}$ and $v_i$, and for $i = 1, \ldots, k - 1$, the edges $e_i, e_{i+1}$ form a transit pair at $v_i$, which means that one of $e_i, e_{i+1}$ enters and the other leaves $v_i$. As before, an edge-simple walk is referred to as a path.

Now we associate to $G_\ell$ a BD-graph $H$ with edge capacities $c: EH \rightarrow \mathbb{Z}_+$, as follows (see Fig. 1 for an illustration). Each noncentral node $v \in VG_\ell - V^s$ generates two nodes $v^1, v^2$ in $H$. They are connected by an edge (arc) $e_v$ going from $v^1$ to $v^2$ and having the capacity equal to $c(v)$. We say that $e_v$ inherits the capacity of the node $v$. For $s \in T$, the set $T^s := \{v^1, v^2 \mid v \in V^s\}$ in $H$ is called the zone of $s$, similar to $V^s$ in $G$.

Consider an edge $e = uv \in EG_\ell$. Let $u, v \in V^s$ for some $s \in T$ and assume for definiteness that $\pi(u) < \pi(v)$ (note that $\ell(uv) > 0$ implies $\pi(u) \neq \pi(v)$; this is where the strict positivity of the cost function $a$ is important). Then $e$ generates in $H$ an edge (arc) going from $u^2$ to $v^1$, and we assign infinite capacity to it. (By “infinite capacity” we mean a sufficiently large positive integer.) Now let $u \in V^s$ and $v \in V^t$ for distinct $s, t \in T$. Then $e$ generates an infinite capacity edge $\overrightarrow{u^2} \overleftarrow{v^2}$ (leaving both $u^2$ and $v^2$).

The transformation of central nodes is less straightforward. Each $w \in V^2$ generates in $H$ a so-called gadget, denoted by $\Gamma_w$. It consists of $|T| + 1$ nodes; they correspond to $w$ and the elements of $T$ and are denoted as $\theta_w$ and $\theta_{w,s}$, $s \in T$. The edges of $\Gamma_w$ are: a loop $e_w$ leaving $\theta_w$ (twice) and, for each $s \in T$, an edge $e_{w,s}$ going from $\theta_{w,s}$ to $\theta_w$, called the $s$-leg in the gadget. Each edge in $\Gamma_w$ is endowed with the capacity equal to $c(w)$. Each gadget $\Gamma_w$ is connected to the remaining part of $H$ as follows. For each edge of the form $vw$ in $G_\ell$, we know that $v \in V^s$ for some $s \in T$ (by the construction of $G_\ell$). Then $vw$ generates an infinite capacity edge (arc) going from $v^2$ to $\theta_{w,s}$.

Finally, we add to $H$ an extra node $q$, regarding it as the source, and for each $s \in T$, draw an infinite capacity edge (arc) from $q$ to $s^1$.

The obtained BD-graph $H$ captures information about the $\ell$-geodesics in $G$. Namely, each $\ell$-geodesic $P$ going from $s$ to $t$ induces a unique closed $q$-$q$ walk $\overrightarrow{P}$ in $H$. The first and the last edges of $\overrightarrow{P}$ are $\overrightarrow{q} \overrightarrow{s^1}$ and $\overrightarrow{t^1} \overrightarrow{q}$, respectively. For a noncentral node $v$ in $P$, $\overrightarrow{P}$ traverses the edge $\overrightarrow{v^1} \overrightarrow{v^2}$. An edge $uv \in EP$ with $\pi(u) < \pi(v)$ inside a zone induces the edge $\overrightarrow{u^2} \overrightarrow{v^1}$. An edge $uv \in EP$ connecting different zones (if any) induces the edge $\overrightarrow{u^2} \overrightarrow{v^2}$ in $\overrightarrow{P}$. Finally, suppose $P$ traverses a central node $w \in V^s$ and
let $uw, vw \in EG_{\ell}$ be the edges of $P$ incident to $w$. By Lemma 2.2, $u \in V^s$ and $v \in V^t$ for some $s \neq t$. Then the sequence of nodes $u, w, v$ in $P$ generates the subpath in $\overline{P}$ with the sequence of edges $u^2 \ell_{w,s}, e_{w,s}, e_{w,t}, \ell_{w,t} v^2$.

The resulting walk $\overline{P}$ is edge-simple, so it is a closed path. Conversely, let $Q$ be a (nontrivial) $q$-$q$ walk in $H$. One can see that $Q$ with $q$ removed is concatenated as $Q_1 \circ Q' \circ Q_2$, where $Q_1$ is a directed path within a zone $V^w$, $Q_2$ is reverse to a directed path within a zone $V^t$ (with possibly $s = t$), and $Q'$ either (i) is formed by an edge $u^2 v^2$ connecting these zones (in which case $s \neq t$), or (ii) is the walk with the sequence of edges $e_{w,s}, e_{w,t}$, for some central node $w$ of $G_{\ell}$. Moreover, the image in $G$ of each of $Q_1, Q_2$ is an $\ell$-shortest path. When $s = t$ happens in case (ii), $Q$ traverses the edge $e_{w,s}$ twice. In all other cases, $Q$ is edge-simple and its image in $G$ is an $\ell$-shortest $T$-path (a $\lambda$-geodesic).

These observations show that there is a natural bijection between the $\ell$-geodesics in $G$ and the (nontrivial) $q$-$q$ paths in $H$.

We will refer to the BD-graph $H$ described above as the compact BD-graph related to $G_{\ell}$; it will be essentially used to devise an efficient algorithm for solving $(N_{\lambda})$ in Section 4. Besides, in the proof of the primal integrality (with $c$ even) in Section 5, we will deal with
a modified BD-graph. It is obtained from $H$ as above by replicating each gadget $\Gamma_w$ into $c(w)$ copies $\Gamma_{w,i}$, $i = 1, \ldots, c(w)$, called the $i$-gadgets generated by $w$. More precisely, to construct $\Gamma_{w,i}$, we make $i$-th copy $\theta_{w,i}$ of the node $\theta_w$, $i$-th copy $e_{w,i}$ of the loop $e_w$ leaving $\theta_{w,i}$ (twice), and $i$-th copy $e_{w,s,i}$ of each leg $e_{w,s}$, $s \in T$, where $e_{w,s,i}$ goes from $\theta_{w,i}$ to $\theta_{w,i}$ (so $\theta_{w,s}, s \in T$, are the common nodes of the created 1-gadgets). All edges in these 1-gadgets are endowed with unit capacities.

We keep notation $H$ for the constructed graph and call it the expensive BD-graph related to $G_t$. Also we keep notation $c$ for the edge capacities in $H$. There is a natural relationship between the $q$-$q$ walks (paths) in both versions of $H$. The 1-gadgets created from the same central node $w$ of $G_t$ are isomorphic, and for any $i, j = 1, \ldots, c(w)$, there is an automorphism of $H$ which swaps $\theta_{w,i}$ and $\theta_{w,j}$ and is invariant on the other nodes.

### 3.2 Bidirected flows

Let $\Gamma$ be a bidirected graph. Like in usual digraphs, $\delta^\text{in}(v)$ and $\delta^\text{out}(v)$ denote the sets of edges in $\Gamma$ entering and leaving $v \in V\Gamma$, respectively. A loop $e$ at $v$, if any, is counted twice in $\delta^\text{in}(v)$ if $e$ enters $v$, and twice in $\delta^\text{out}(v)$ if $e$ leaves $v$; hence $\delta^\text{in}(v)$ and $\delta^\text{out}(v)$ are actually multisets. (Recall that we do not allow a loop which simultaneously enters and leaves a node.)

Let $q$ be a distinguished node with $\delta^\text{in}(q) = \emptyset$ in $\Gamma$ (the source) and let the edges of $\Gamma$ have integer capacities $c: E\Gamma \to \mathbb{Z}_+$. A bidirected $q$-flow, or a BD-flow for short, is a function $f: E\Gamma \to \mathbb{Q}_+$ satisfying $\text{div}_f(v) = 0$ for all nodes $v \in V\Gamma - \{q\}$; and the value of $f$ is defined to be $\text{div}_f(q)$ (cf. [GK04]). Here

$$\text{div}_f(v) := f(\delta^\text{out}(v)) - f(\delta^\text{in}(v))$$

is the divergence of $f$ at $v$. Note that if $e$ is a loop at $v$ then $e$ contributes $\pm 2f(e)$ in $\text{div}_f(v)$. If $f(e) \leq c(e)$ for all $e \in E\Gamma$ then $f$ is called feasible. In addition, if $f$ is integer-valued on all edges then we refer to $f$ as an integer bidirected $q$-flow, or an IBD-flow. One can see that finding a fractional (resp. integer) BD-flow of the maximum value is equivalent to constructing a maximum fractional (resp. integer) packing of closed $q$-$q$ walks (they leave $q$ twice).

Return to an optimal solution $l$ to $(D_\lambda)$, and let $\ell := \pi + T$. Consider the (expensive or compact) BD-graph $H$ related to $G_t$, and the capacity function $c$ on the edges of $H$ (constructed from the node capacities $c$ of $G$). The above correspondence between $\ell$-geodesics in $G$ and $q$-$q$ paths in $H$ is extended to $\ell$-geodesic multilows in $G$ and certain $q$-flows in $H$ (where $q$ is the source in $H$ as before). More precisely, let $F$ be a (fractional) $\ell$-geodesic multilow in $G$ represented by a collection of $\ell$-geodesics $P_i$ and weights $\alpha_i := F(P_i)$, $i = 1, \ldots, m$ (cf. (1.1)). Then each $P_i$ determines a $q$-$q$ path $\overline{P}_i$ in $H$, and $f := \alpha_1\chi_{E\overline{P}_1} + \ldots + \alpha_m\chi_{E\overline{P}_m}$ is a BD-flow in $H$; we say that $f$ is generated by $F$ (note that $\text{val}(f) = 2\text{val}(F)$). Furthermore, $f$ is feasible if $F$ is such, and for each central node $w \in V^2$, the following relations hold:

$$\sum_{s \in T} f(e_{w,s}) = 2f(e_w) \quad \text{and} \quad f(e_{w,s}) \leq f(e_w) \text{ for each } s \in T.$$  

Considering an arbitrary BD-flow $f$ in $H$, we say that $f$ is good if it satisfies (3.2) for all $w \in V^2$ (here the second relation in (3.2) is important, while the first one obviously holds for any BD-flow). The following assertion is of use.
Lemma 3.1 Let \( f \) be a good BD-flow in \( H \). Then \( f \) is generated by an \( \ell \)-geodesic multiflow \( F \) in \( G \). Moreover, if \( f \) is integral, then it is generated by an integer \( \ell \)-geodesic multiflow \( F \). In both cases, \( F \) can be found in \( O(|V_H| \cdot |E_H|) \) time.

Proof. Suppose there is a central node \( w \in V^2 \) such that \( f(e_w) > 0 \). Let us say that 
\( p \in T \) dominates at \( w \) (w.r.t. \( f \)) if \( f(e_{w,p}) = f(e_w) \). From (3.2) it follows that there exist distinct \( s,t \in T \) such that \( f(e_{w,s}), f(e_{w,t}) > 0 \) and none of \( p \in T - \{s,t\} \) dominates at \( w \). Choose such \( s,t \). Build in \( H \) a maximal walk \( Q \) starting with \( \theta_w, e_{w,s}, \theta_w, s, \ldots \) and such that \( f(e) > 0 \) for all edges \( e \) of \( Q \). It is easily seen from the construction of \( H \) that \( Q \) is edge-simple, terminates at \( q \), and have all vertices in \( V^s \), except for \( \theta_w, \theta_w, s, \ldots \) and \( q \). Build a similar walk (path) \( Q' \) starting with \( \theta_w, e_{w,t}, \theta_w, t \). Then the concatenation of the reverse to \( Q \), the loop \( e_w \) and the path \( Q' \) is a \( q-q \) path \( \tilde{P} \) and its image \( P \) in \( G \) is an \( \ell \)-geodesic (from \( s \) to \( t \)).

Assign the weight of \( P \) to be the maximum number \( \alpha \) subject to two conditions: (i) \( \alpha \leq f(e) \) for each \( e \in E_P \); and (ii) the flow \( f' := f - \alpha \chi_P \) is still good. If \( \alpha \) is determined by (i), we have \( |\text{supp}(f')| < |\text{supp}(f)| \) (where \( \text{supp}(\varphi) := \{x \mid \varphi(x) \neq 0\} \)), whereas if \( \alpha \) is determined by (ii), there appears \( p \in T \) dominating at \( w \) (w.r.t. \( f' \)). If \( f'(e_w) > 0 \), repeat the procedure for \( f' \) and \( w \), otherwise apply the procedure to \( f' \) and another \( w' \in V^2 \), and so on. (Note that if, in the process of handling \( w \), the current weight \( \alpha \) is determined by (ii), then the weights of all subsequent paths through \( e_w \) are already determined by (i); this will provide the desired complexity.)

Eventually, we come to a good flow \( \tilde{f} \) with \( \tilde{f}(e_w) = 0 \) for all \( w \in V^2 \). This \( \tilde{f} \) is decomposed into a sum of flows along \( q-q \) paths in a straightforward way, in \( O(|V_H| \cdot |E_H|) \) time (like for usual flows in digraphs). Taking together the images in \( G \) of the constructed weighted \( q-q \) paths, we obtain a required \( \ell \)-geodesic multiflow \( F \). The running time of the whole process is \( O(|V_H| \cdot |E_H|) \), and if \( f \) is integral, then the weights \( \alpha \) of all paths are integral as well. (Integrality of a current weight \( \alpha \) subject to integrality of a current flow \( f \) is obvious when \( \alpha \) is determined by (i), and follows from the fact, implied by (3.2), that for any \( p \in T \), \( \sum_{s \neq p} f(e_{w,s}) - f(e_{w,p}) \) is even, when \( \alpha \) is determined by (ii).)

Remark 3.2 In case of an expensive BD-graph \( H \), any feasible IBD-flow \( f \) is good.
Indeed, for any \( 1 \)-gadget \( \Gamma_w \) in \( H \), we have \( c(e_{w,v}) = 1 \) and, therefore, \( f(e_w) \in \{0,1\} \).
The second relation in (3.2) is trivial when \( f(e_w) = 0 \), and follows from the constraints \( f(e_{w,s})\leq c(e_{w,s}) = 1 \) (\( s \in T \)) when \( f(e_w) = 1 \).

Define the following subset of edges in \( H \):

\[
E_0 := \{e_v \mid v \in VG, \ l(v) > 0\}.
\]

For an optimal (possibly fractional) solution \( F \) to \( (N_\lambda) \) and a node \( v \in VG \) with \( l(v) > 0 \), we have \( \tilde{F}(v) = c(v) \) (by (2.7)); so the edge \( e_v \) of \( H \) corresponding to \( v \) is saturated by the BD-flow \( f \) generated by \( F \), i.e. \( f(e_v) = c(e_v) \). We call the edges in \( E_0 \) locked.

Thus, the graph \( H \) admits a (fractional) good feasible BD-flow saturating the locked edges. The following strengthening is crucial.

Proposition 3.3 There exists a (fractional) good feasible IBD-flow in \( H \) that saturates all locked edges.
A proof of this proposition involves an additional graph-theoretic machinery and will be given in Section 5. Assuming its validity, we immediately obtain Theorem 2.1 from Lemma 3.1.

4 Solving \((N, \lambda)\) in strongly polynomial time

In this section we devise a strongly polynomial algorithm for solving the primal parametric problem \((N, \lambda)\). As before, we assume that \(a\) and \(\lambda\) are integral and that the node capacities \(c\) are even, so our goal is to find an integer optimal multflow.

The algorithm starts with computing a (fractional) optimal dual solution \(l\) and constructing the BD-graph \(H\) w.r.t. the length function \(\ell := \overline{\nu} + \overline{\ell}\). Then it finds a good IBD-flow \(f\) in \(H\) saturating the locked edges (assuming validity of Proposition 3.3). Applying the efficient procedure as in the proof of Lemma 3.1 to decompose \(f\) into a collection of paths with integer weights, we will obtain an integer optimal solution to \((N, \lambda)\).

To provide the desired complexity, we shall work with \(H\) given in the compact form (defined in Subsection 3.1). The core of our method consists in finding the load function of some integer optimal multflow \(F\) in \(G\) (without explicitly computing \(F\) itself). This function will just generate the desired IBD-flow in \(H\). We describe the stages of the algorithm in the subsections below.

4.1 Constructing an optimal dual solution

Problem \((D, \lambda)\) straightforwardly reduces to a “compact” linear program, as follows. Besides variables \(l(v) \in \mathbb{Q}_+ (v \in VG)\), assign a variable \(\varphi_s(v) \in \mathbb{Q}\) to each terminal \(s \in T\) and node \(v\) (a sort of “distance” of \(v\) from \(s\)). Consider the following problem (where \(l\) and \(\overline{\nu}\) are defined according to (2.2)):

(4.1) Minimize \(c \cdot l\) subject to the following constraints:

\[
\varphi_s(u) - \varphi_s(v) \leq \overline{\nu}(e) + \overline{\ell}(e)
\]

\[
\varphi_s(v) - \varphi_s(u) \leq \overline{\nu}(e) + \overline{\ell}(e) \text{ for each } e = uv \in EG;
\]

\[
\varphi_s(t) - \varphi_s(s) \geq \lambda \text{ for all } s, t \in T, s \neq t.
\]

Lemma 4.1 Programs \((D, \lambda)\) and (4.1) are equivalent.

Indeed, if \((l, \varphi)\) is a feasible solution to (4.1) then, obviously, \(l\) is a feasible solution to \((D, \lambda)\). Conversely, let \(l\) be a feasible solution to \((D, \lambda)\). For \(v \in VG\) and \(s \in T\), define \(\varphi_s(v) := \text{dist}_\ell(s, v)\), where \(\ell := \overline{\ell} + \overline{\nu}\). It is easy to check that \((l, \varphi)\) is a feasible solution to (4.1).

The size of the constraint matrix in (4.1) (written in binary notation) is polynomial in \(|VG|\). Therefore, \((D, \lambda)\) is solvable in strongly polynomial time by use of Tardos’ version of the ellipsoid method. (This remains valid when \(a\) and \(\lambda\) are nonnegative rational numbers.)
4.2 Computing the load function of an optimal multiflow

The following fact is of importance.

Lemma 4.2. One can find, in strongly polynomial time, a function \( g : V G \rightarrow \mathbb{Z}_+ \) such that \( g(v) = \tilde{F}(v) \) for all \( v \in V G \), where \( F \) is some integer optimal multiflow in \( (N_\lambda) \).

Proof. We explain that in order to construct the desired \( g \), it suffices to compare two optimal objective values: one for the original (integer) costs \( a \) and the other for certain perturbed costs \( a_\varepsilon \). These values are computed by solving the corresponding dual problems by the method described in the previous subsection.

More precisely, let \( v_1, \ldots, v_n \) be the nodes of \( G \). Let \( U := \max_i c(v_i) + 2 \), define \( \varepsilon(v_i) := \frac{1}{U^{i+1}} \), \( i = 1, \ldots, n \), and define the cost function \( a_\varepsilon \) on \( VG \) to be \( a + \varepsilon \). Then for any integer feasible multiflow \( F \), we have

\[
0 \leq \Phi(F, a, \lambda) - \Phi(F, a_\epsilon, \lambda) = \sum_i \tilde{F}(v_i)\varepsilon(v_i) < U^{-1} + U^{-2} + \ldots + U^{-n} < 1.
\]

This and the fact that \( \Phi(F, a, \lambda) \) is an integer (as \( F, a, \lambda \) are integral) imply that if \( F \) is optimal for \( a_\varepsilon \), then \( F \) is optimal for \( a \) as well. (An integer optimal multiflow for even capacities \( c \) exists by Theorem 2.1.) Moreover, for such an optimal \( F \), the number \( r := \sum_i \tilde{F}(v_i)\varepsilon(v_i) \) is computed in strongly polynomial time, since it is equal to \( c \cdot l - c \cdot l_\varepsilon \), where \( l \) and \( l_\varepsilon \) are optimal dual solutions for \( a \) and \( a_\varepsilon \), respectively. Here we use the LP duality equalities \( \Phi(F, a, \lambda) = c \cdot l \) and \( \Phi(F, a_\varepsilon, \lambda) = c \cdot l_\varepsilon \). Also the size of binary encoding of \( a_\varepsilon \) is bounded by that of \( a \) times a polynomial in \( n \), so the dual problem with \( a_\varepsilon \) is solved in strongly polynomial time w.r.t. the original data.

Hence, we have \( rU^{n+1} = \sum_i \tilde{F}(v_i)U^{n-i} \). The number \( rU^{n+1} \) is an integer and, in view of \( \tilde{F}(v_i) \leq c(v_i) < U \) for each \( i \), the \( n \) coefficients in its base \( U \) decomposition (the representation via degrees of \( U \)) are just \( \tilde{F}(v_1), \ldots, \tilde{F}(v_n) \), thus giving \( g \).

Recall that together with a node load function each multiflow \( F \) also induces its edge counterpart (see (1.3)). Lemma 4.2 can be strengthened as follows.

Lemma 4.3 One can find, in strongly polynomial time, a function \( g : V G \cup E G \rightarrow \mathbb{Z}_+ \) such that \( g(v) = \tilde{F}(v) \) for all \( v \in V G \) and \( g(e) = \tilde{F}(e) \) for all \( e \in E G \), where \( F \) is some integer optimal multiflow \( F \) in \( (N_\lambda) \).

Proof. Split each edge \( e = uv \) of \( G \) into two edges \( u x_e, x_e v \) in series and assign to each new node \( x_e \) the capacity \( c(x_e) := \min\{c(u), c(v)\} \) and the cost \( a(x_e) := 0 \). Clearly this transformation does not affect the problem in essence. The node load function, which can be found in strongly polynomial time by Lemma 4.2, yields the desired node and edge load functions in the original graph \( G \).

4.3 Constructing an optimal primal solution

Now we explain how to find, in strongly polynomial time, an integer optimal multiflow solving \( (N_\lambda) \) (for a graph \( G \), even node capacities \( c \), rational node costs \( a \), and an integer parameter \( \lambda \)) by using an optimal dual solution \( l \) and a function \( g \) as in Lemma 4.3. For this \( g \), there exists an integer \( \ell \)-geodesic multiflow \( F' \) in \( G \) satisfying \( \tilde{F}'(v) = g(v) \) for all
$v \in VG$ and $\tilde{F}'(e) = g(e)$ for all $e \in EG$, where $\ell := \pi + 1$. Our goal is to construct one of such multiflows explicitly.

To do this, we consider the compact BD-graph $H$ related to $G_\ell$ (see Subsection 3.1) and put $f$ to be the function on $EH$ corresponding to $g$. More precisely, let $E'$ be the subset of edges of $H$ neither incident to $q$ nor contained in the gadgets $\Gamma_w$ ($w \in V^2$). By the construction of $H$, there is a natural bijection $\gamma$ of $E'$ to the set $(VG_\ell - V^2) \cup EG_\ell$. For each $e \in E'$, we set $f(e) := g(\gamma(e))$. In their turn, the values of $f$ on the edges of a gadget $\Gamma_w$ are assigned as follows: for the loop $e_w$ at $\theta_w$, set $f(e_w) := g(w)$, and for each $s \in T$, set $f(e_{w,s}) := \sum(e : e \in E_{s,w})$, where $E_{s,w}$ is the set of edges in $G_\ell$ connecting $V^s$ and $w$. Finally, for each $s \in T$, we set $f(qs) := h(s)$.

Using the fact that the function $g$ on $VG \cup EG$ is determined by some integer optimal ($\ell$-geodesic) multiflow $F'$, it follows that the obtained function $f$ on $EH$ is integer-valued and has zero divergency at all nodes different from $q$. So $f$ is an IBD-flow in $H$. Moreover, $f$ is generated by $F'$ as above; in particular, $f$ is good (i.e. satisfies (3.2)). By Lemma 3.1, we can find, in strongly polynomial time, an integer $\ell$-geodesic multiflow $F$ generating $f$. Then $F$ and $F'$ have the coinciding node and edge load functions, and the optimality of $F'$ implies that $F$ is an integer optimal solution to $(N_\lambda)$ as well, as required.

5 Proof of Proposition 3.3

To complete the proof of Theorem 2.1 it remains to prove Proposition 3.3, which claims the existence of an IBD-flow saturating the “locked” edges. We eliminate the lower capacity constraints (induced by the locked edges) by reducing the claim to the existence of an IBD-flow with a certain prescribed value.

5.1 Maximum IBD-flows

Let $\Gamma$ be a bidirected graph with a distinguished source $q$ and edge capacities $c : ET \rightarrow \mathbb{Z}_+$, as described in Subsection 3.2. The classic max-flow min-cut theorem states that the maximum flow value is equal to the minimum cut capacity. A bidirected version of this theorem involves a somewhat more complicated object, called an odd barrier. In this subsection we give its definition and state the crucial properties (in Theorems 5.1, 5.2, 5.3) that will be used in the upcoming proof of Proposition 3.3. These properties are nothing else than translations, to the language of bidirected graphs, of corresponding properties established for integer symmetric flows in skew-symmetric graphs, as we will explain in the Appendix.

Let $X \subseteq V \Gamma - \{q\}$. The flip at (the nodes of) $X$ modifies $\Gamma$ as follows: for each node $v \in X$ and each edge $e$ incident to $v$, we reverse the direction of $e$ at $v$ (while preserving the directions of edges at nodes in $VG - X$). For example, if $e = \overrightarrow{u v}$ and $u, v \in X$ then $e$ becomes $\overrightarrow{v u}$, and if $e = \overrightarrow{u v}$ and $u \notin X \ni v$ then $e$ becomes $\overrightarrow{u v}$. BD-graphs $\Gamma$ and $\Gamma'$ are called equivalent if one is obtained by a flip from the other. Note that flips do not affect bidirected walks in $\Gamma$ in essence and do not change the maximum value of an IBD-flow in it. We will essentially use flips to simplify requirements in the definition of odd barriers below.

Next, we employ a special notation to designate certain subsets of edges. For $X, Y \subseteq V \Gamma$, let $[X, Y]$ denote the set of edges with one endpoint in $X$ and the other in $Y$. We
will often add arrows above $X$ and/or $Y$ to indicate the subset of edges in $[X,Y]$ directed in one or another way. For example, $[X, Y]$ denotes the set of edges that enter both $X$ and $Y$, $[X, Y]$ denotes the set of edges leaving $X$ and having the other endpoint in $Y$ (where the direction is arbitrary), and $[X, X]$ denotes the set of edges that leave $X$ at both endpoints (including twice leaving loops). When $Y = VT - X$, the second term in the brackets may be omitted: $[X]$, $[X]$, and $[X]$ stand for $[X, VT - X]$, $[X, VT - X]$, and $[X, VT - X]$, respectively. Finally, for a function $\varphi$ on the edges, we write $\varphi([X,Y])$ (rather than $\varphi([X,Y])$) for $\sum_{e \in [X,Y]} \varphi(e)$.

A tuple $B = (\Gamma' | A, M; B_1, \ldots, B_k)$, where $\Gamma'$ is some BD-graph equivalent to $\Gamma$, is called an odd barrier for $\Gamma$ if the following conditions hold with respect to $\Gamma'$ (see Fig. 2):

\begin{align}
\text{(5.1) } & \text{(i) } A, M, B_1, \ldots, B_k \text{ give a partition of } VT' = VT, \text{ and } q \in A. \\
& \text{(ii) For each } i = 1, \ldots, k, \text{ } c[\widetilde{A}, B_i] \text{ is odd.} \\
& \text{(iii) For distinct } i, j = 1, \ldots, k, \text{ } c[B_i, B_j] = 0. \\
& \text{(iv) For each } i = 1, \ldots, k, \text{ } c[B_i, M] = 0.
\end{align}

The capacity of $B$ is defined to be

\begin{equation}
(5.2) \quad c(B) := 2c[\widetilde{A}, \widetilde{A}] + c[\widetilde{A}] - k.
\end{equation}

**Theorem 5.1 (Max IBD-Flow Min Odd Barrier Theorem)** For $\Gamma, c, q$ as above, the maximum IBD-flow value is equal to the minimum odd barrier capacity. A (feasible) IBD-flow $g$ and an odd barrier $B = (\Gamma' | A, M; B_1, \ldots, B_k)$ for $\Gamma$ have maximum value and minimum capacity, respectively, if and only if the following conditions hold with respect to $\Gamma'$:

\begin{align}
\text{(i) } & g[\widetilde{A}, \widetilde{A}] = c[\widetilde{A}, \widetilde{A}] \text{ and } g[\widetilde{A}, \widetilde{A}] = 0; \\
\text{(ii) } & g[\widetilde{A}, M] = c[\widetilde{A}, M] \text{ and } g[\widetilde{A}, M] = 0; \\
\text{(iii) for each } i = 1, \ldots, k, \text{ either } g[\widetilde{A}, B_i] = c[\widetilde{A}, B_i] - 1 \text{ and } g[\widetilde{A}, B_i] = 0, \text{ or } g[\widetilde{A}, B_i] = c[\widetilde{A}, B_i] \text{ and } g[\widetilde{A}, B_i] = 1.
\end{align}
Note that there may exist many minimum capacity odd barriers for $\Gamma, c, q$. It is well-known that in a usual arc-capacitated digraph with a source $s$ and a sink $t$, the set of nodes reachable by paths from $s$ in the residual digraph of a maximum $s$-$t$ flow $f$ determines a minimum capacity $s$-$t$ cut. Moreover, this minimum cut does not depend on the choice of $f$ and, therefore, may be regarded as the canonical one.

A similar phenomenon takes place for maximum IBD-flows and minimum odd barriers (and we will essentially use this in the proof of Proposition 3.3). To describe this, consider an IBD-flow $g$ in $\Gamma$. The residual BD-graph $\Gamma_g$ endowed with the residual capacities $c_g: \mathcal{E}_g \rightarrow \mathbb{Z}_+$ is constructed in a similar way as for usual flows. More precisely, $\mathcal{V}_{\Gamma_g} = \mathcal{V}_\Gamma$ and the edges of $\Gamma_g$ are as follows:

\[(5.3) \quad (i) \text{ each edge } e \in \mathcal{E}_g \text{ with } g(e) < c(e) \text{ whose residual capacity is defined to be } \]
\[c_g(e) := c(e) - g(e), \text{ and } \]
\[(ii) \text{ the reverse edge } e^R \text{ to each edge } e \in \mathcal{E}_g \text{ with } g(e) > 0; \text{ the directions of } \]
\[e^R \text{ at the endpoints are reverse to those of } e \text{ and the residual capacity is } \]
\[c_g(e^R) := g(e). \]

A bidirected walk $P$ in $\Gamma_g$ is called $c_g$-simple if $P$ passes each edge $e$ at most $c_g(e)$ times. If $P$ is a $c_g$-simple closed $q$-$q$ walk leaving its end $q$ twice, we can increase the value of $g$ in $\Gamma$ by 2, by sending one unit of flow along $P$. So the existence (in $\Gamma_g$) of such a walk $P$, which is called $(\Gamma, g)$-residual, implies that $g$ is not maximum. A converse property holds as well.

**Theorem 5.2** An IBD-flow $g$ in $\Gamma$ is maximum if and only if there is no $(\Gamma, g)$-residual walk.

When we are given a maximum IBD-flow $g$, a certain minimum odd barrier can be constructed by considering the residual graph $\Gamma_g$. Namely, let $\overrightarrow{\Gamma}_{\Gamma_g}$ (resp. $\overleftarrow{\Gamma}_{\Gamma_g}$) be the set of nodes $v$ that are reachable by a $(\Gamma, g)$-residual $q$-$v$ walk that leaves $q$ and enters $v$ (resp. leaves both $q$ and $v$). Then $q \notin \overrightarrow{\Gamma}_{\Gamma_g}$, by the maximality of $g$.

**Theorem 5.3** Let $g$ be a maximum IBD-flow for $\Gamma, c, q$. Define $A := (\overrightarrow{\Gamma} - \overleftarrow{\Gamma}) \cup (\overleftarrow{\Gamma} - \overrightarrow{\Gamma})$ and $M := \mathcal{V}_\Gamma - (\overrightarrow{\Gamma} \cup \overleftarrow{\Gamma})$, where $\overrightarrow{\Gamma} := \overrightarrow{\Gamma}_{\Gamma_g}$ and $\overleftarrow{\Gamma} := \overleftarrow{\Gamma}_{\Gamma_g}$. Let $B_1, \ldots, B_k$ be the node sets of weakly connected components of the underlying undirected subgraph of $\Gamma_g$ induced by $\overrightarrow{\Gamma} \cap \overleftarrow{\Gamma}$. Define $\Gamma'$ to be the BD-graph obtained from $\Gamma$ by flipping the set $\overrightarrow{\Gamma} - \overleftarrow{\Gamma}$ (contained in $A$). Then $\mathcal{B}_g := (\Gamma' | A, M; B_1, \ldots, B_k)$ is a minimum odd barrier.

An important fact is that the minimum odd barrier $\mathcal{B}_g$ does not depend on $g$, and we refer to it as the canonical odd barrier for $\Gamma, c, q$.

**Theorem 5.4** The sets $\overrightarrow{\Gamma}_{\Gamma_g}$ are same for all maximum IBD-flows $g$ in $\Gamma$, and similarly for the sets $\overleftarrow{\Gamma}_{\Gamma_g}$, the minimum odd barriers $\mathcal{B}_g$, and the graphs $\Gamma'$ obtained from $\Gamma$ by flipping $\overrightarrow{\Gamma}_{\Gamma_g} - \overleftarrow{\Gamma}_{\Gamma_g}$.
5.2 Proof of Proposition 3.3

In fact, we have freedom of choosing any of the two forms (expensive or compact) of $H$ to prove Proposition 3.3 in full, as it is easy to see that the claims in these cases are reduced to each other. We prefer to deal with the expensive form, taking advantage from certain nice structural features arising in this case. One reason for our choice is that any IBD-flow in the expensive $H$ is automatically good, as explained in Remark 3.2.

We know that there exists a good fractional bidirected $q$-flow $f$ in $H$ that saturates the set $E_0$ of locked edges, and our goal is to show the existence of an IBD-flow saturating $E_0$. Recall that any edge $e \in E_0$ is generated by some node $v$ of $G$, i.e. $e = e_v$.

It will be convenient for us to construct the desired IBD-flow without explicitly imposing the “lower capacities” on the locked edges. For this purpose, we modify $H$ as follows.

First, we add a loop $\overrightarrow{q} \overleftarrow{q}$ with infinite capacity (entering $q$ twice). Also we add to $H$ a node $z$, which is regarded as a new source.

Second, let $E_0$ contain an edge $e_v = \overrightarrow{v^1} \overleftarrow{v^2}$ generated by a vertex $v \in VG_\ell$ in some zone $V^s$, $s \in T$. We delete $e_v$ from $H$ and, instead, add two edges $\overrightarrow{v^1 \overrightarrow{v}}$ and $\overleftarrow{v^2}$ with capacity $c(v)$ each.

Third, let $E_0$ contain the loops $e_{w^i}$ (for $i = 1, \ldots, c(w)$) for some central node $w$ of $G_\ell$. We replace each $e_{w^i}$ (having unit capacity) by edge $z \theta_{w^i}$ with capacity 2; we call it the root edge at $\theta_{w^i}$.

We denote the resulting BD-graph by $H^1$ and keep the previous notation $c$ for its edge capacities. The above $q$-flow $f$ is transformed, in an obvious way, into a feasible $z$-flow in $H^1$, denoted by $f$ as before. Note that this $f$ saturates all edges created from those in $E_0$ (i.e. from $e_v$ and $e_{w^i}$ as above); these edges leave $z$ and the value of $f$ is maximum among the feasible $z$-flows in $H^1$ and is equal to $2c(E_0)$.

Let $g$ be a maximum IBD-flow in $H^1$. We are going to prove that $\text{val}(f) = \text{val}(g)$. This would imply that the corresponding IBD-flow in $H$ saturates $E_0$ as required. To this aim, consider the canonical odd barrier $B = (H^2 | A, M; B_1, \ldots, B_k)$ for $H^1, c, z$ (see Theorem 5.4). Here $H^2$ is the BD-graph (with the source $z$) obtained from $H^1$ according to Theorem 5.3 (i.e. $H^2 := \Gamma'$ for $\Gamma := H^1$). From now on, speaking of edge directions, the capacities $c$ and the flow $g$, we mean those in $H^2$, unless explicitly stated otherwise.

We have (cf. (5.2))

\begin{equation}
\text{val}(g) = c(B) = 2c[\overrightarrow{A}, \overleftarrow{A}] + c[\overrightarrow{A}] - k.
\end{equation}

The following assertion is crucial.

**Lemma 5.5** For each $p = 1, \ldots, k$:

(i) $B_p = \{ \theta_{w^i} \}$ for some $w \in V^s$ and $i \in \{1, \ldots, c(w)\}$;

(ii) $e_{w^i}$ is not locked (so $H^1$ contains the loop $e_{w^i}$ but not the root edge at $\theta_{w^i}$);

(iii) among the edges (legs) connecting $A$ and $B_p$, one edge leaves $A$ and the other edges enter $A$.

15
Proof. By the constructions of $H$ and $H^1$, for any $w \in V^1$ and distinct $i, j = 1, \ldots, c(w)$, there is an automorphism $\pi = \pi_{w,i,j}$ of $H^1$ that swaps $\theta_{wi}$ and $\theta_{wj}$ and is invariant on the other nodes. Also $\pi$ respects the capacities in $H^1$, and the function $\tilde{g}$ induced by $g$ under $\pi$ (i.e. $\tilde{g}(e) := g(\pi(e))$) is again a maximum IBD-flow in $H^1$. Since $\mathcal{B}$ is canonical, it follows from Theorem 5.4 that

\begin{equation}
(5.5) \quad \overline{R}_{H^1,g} = \overline{R}_{H^1,\tilde{g}}, \quad \overline{R}_{H^1,g} = \overline{R}_{H^1,\tilde{g}}, \quad \overline{R}_{H^1,g} \cup \overline{R}_{H^1,g} = A \cup B_1 \cup \ldots \cup B_k.
\end{equation}

The nodes in $\overline{R}_{H^1,g} - \overline{R}_{H^1,g}$ are flipped when constructing $H^2$ from $H^1$. Then (5.5) and Theorem 5.3 imply that for $i, j$ as above,

\begin{enumerate}
\item[(a)] $\theta_{wi}$ is flipped if and only if $\theta_{wj}$ is flipped;
\item[(b)] $\theta_{wi} \in A$ if and only if $\theta_{wj} \in A$.
\item[(c)] $\theta_{wi} \in B_1 \cup \ldots \cup B_k$ if and only if $\theta_{wj} \in B_1 \cup \ldots \cup B_k$.
\end{enumerate}

Let $p \in \{1, \ldots, k\}$. Since the capacity $c(\overline{A}, B_p)$ (in $H^2$) is odd, the set $[\overline{A}, B_p]$ contains an edge $e$ with $c(e)$ odd. Any edge in $H^2$ having an odd capacity is either a loop $e_{wi}$ or a leg $e_{w_i,s}$ (regarding “infinite” capacities as even ones).

Obviously, no loop can be “responsible” for the oddness of $c(\overline{A}, B_p)$.

So $e = e_{wi,s} = \theta_{wi} \theta_{ws}$ for some $w \in V^1$, $i \in \{1, \ldots, c(w)\}$ and $s \in T$. Let $\tilde{e}$ denote the edge of $H^1$ corresponding to $e$. Then $\tilde{e}$ leaves $\theta_{ws}$ and enters $\theta_{wi}$ (see Fig. 1(b)). Due to flips, however, this may not be the case for $e$ in $H^2$.

Suppose $\theta_{wi} \in A$ and $\theta_{ws} \in B_p$. Then $e$ leaves $\theta_{wi}$, whence $\theta_{wi}$ is a flipped node in $A$. Now (5.6)(a,b) imply that all $\theta_{wj}$ are flipped nodes belonging to $A$ and that $e_{w_j,s} \in [\overline{A}, B_p]$ for all $j = 1, \ldots, c(w)$. But then $e$ cannot be “responsible” for the oddness of $c(\overline{A}, B_p)$ since $c(w)$ is even.

So we have $\theta_{ws} \in A$ and $\theta_{wi} \in B_p$. Then $e$ leaves $\theta_{ws}$. The edge $\tilde{e}$ leaves $\theta_{wi}$, as well. Hence $\theta_{ws}$ is not flipped. Since $c(w)$ is even, there must be $j \in \{1, \ldots, c(w)\}$ such that $e_{w_j,s} = \theta_{ws} \theta_{wj}$ is not in $[\overline{A}, B_p]$ (for otherwise one may pick another pair $w, i$). Then $\theta_{wj}$ is not in $B_p$. In view of (5.6)(c), $\theta_{wj}$ belongs to a $B$-set in $\mathcal{B}$ different from $B_p$. Considering the automorphisms $\pi = \pi_{w,i,j}$ for all distinct $i, j = 1, \ldots, c(w)$ and using the fact that the canonical barrier $\mathcal{B}$ preserves under $\pi$ (in view of (5.5)), we can conclude that the nodes $\theta_{wi}, \ldots, \theta_{w_{c(w)}}$ belong to different $B$-sets in $\mathcal{B}$. Since these $B$-sets are pairwise disjoint and each automorphism $\pi$ swaps two copies of $\theta_w$, and do not move the remaining nodes in $H^2$, each of these $B$-sets can contain only a single node. Thus, $B_p = \{\theta_{wj}\}$, yielding (i) in the lemma.

Next we show (ii). From the construction of $H^2$ it follows that

\begin{equation}
(5.7) \quad A = \overline{R}_{H^2,g} - \overline{R}_{H^2,\tilde{g}} \quad \text{and} \quad B_1 \cup \ldots \cup B_k = \overline{R}_{H^2,g} \cap \overline{R}_{H^2,\tilde{g}}.
\end{equation}

By the first equality, any $(H^2,g)$-residual walk ending at a node $v \in A$ enters $v$, and by the second equality, there exist an $(H^2,g)$-residual walk $P$ to $\theta := \theta_{wi}$ that enters $\theta$ and an $(H^2,g)$-residual walk $Q$ to $\theta$ that leaves $\theta$. Recall that the residual walks leave the source $z$. Let $a = u \theta$ be the last edge of $P$, and $b = v \theta$ the last edge of $Q$. Define $E'$ (resp. $E''$) to be the set of legs $e = e_{w_i,s}$ with $g(e) = 0$ (resp. $g(e) = 1$). Note that (cf. (5.3))
\[(5.8) \quad \text{(i) if } e \in E' \text{ then } e^R \notin EH^2_g \text{ and } e \text{ enters } \theta \text{ in } H^2_g; \]

\[(\text{ii) if } e \in E'' \text{ then } e \notin EH^2_g \text{ and } e^R \text{ leaves } \theta \text{ in } H^2_g.\]

Supposing the existence of the root edge \( r = \overrightarrow{z \theta} \) (in \( H^1 \) and \( H^2 \)), we can come to a contradiction as follows. Since there is no loop at \( \theta \), both nodes \( u, v \) are in \( A \). Note that the edge \( a \) is different from \( r \) (which leaves \( \theta \)) and from \( r^R \) (which enters \( z \)). Then (5.8) implies that \( a \in E' \). Furthermore, \( a \) is of the form \( \overrightarrow{w \theta} \). For if \( a \) enters \( u \) then the edge of \( P \) preceding \( a \) leaves \( u \), whence the part of \( P \) from \( z \) to \( u \) forms an \( (H^2, g) \)-residual walk leaving \( u \), which is impossible since \( u \in A \).

So \( a \in [A, B_p] \) and \( g(a) = 0 = c(a) - 1 \). Then \( g[A, B_p] = 0 \), by Theorem 5.1(iii). This implies that \( E'' \subseteq [A, B] \). But then the last edge \( b = v \theta \) of the walk \( Q \) as above cannot be reverse to any edge in \( E'' \); for otherwise \( b \) enters \( v \), implying that the part of \( Q \) from \( z \) to \( v \) leaves \( v \). Also \( b \) is neither reverse to an edge in \( E' \) (cf. (5.8)), nor equal to \( r \). The latter is because \( r \in [A, B_p] \), and therefore, \( g(a) < c(a) \) implies \( g(r) = c(r) \) (cf. Theorem 5.1(iii)), whence \( r \notin EH^2_g \). Thus, \( Q \) does not exist. This contradiction yields (ii).

It remains to show (iii). By (ii), we have \( e_w^t \in EH^2 \), and \([A, B_p]\) is exactly the set of legs at \( \theta := \theta_{w^t} \). Suppose \( d := ||[A, B_p]|| \neq 1 \). Then \( d \geq 3 \), since \( c[A, B_p] = d \) is odd. Hence \( g[A, B_p] \geq d - 1 \geq 2 \) (by Theorem 5.1(iii)). Also the fact that all legs enter \( \theta \) together with \( \text{div}_g(\theta) = 0 \) and \( g(e_w^t) \leq 1 \) implies that the only possible case is when \( g(e_w^t) = 1 \), \( g[A, B_p] = 2 \) and \( g[A, B_p] = 0 \). Now take an \( (H^2, g) \)-residual walk \( Q \) to \( \theta \) that leaves \( \theta \), and let \( b \) be its last edge. Then \( b \) is neither the loop \( e_w^t \) (which is saturated), nor reverse to a leg \( e = v \theta \) with \( g(e) > 0 \). Indeed, if \( b = e^R \) then \( b \) enters \( v \) (in view of \( v \in A \) and \( e \in [A, B_p] \)), and hence the part of \( Q \) from \( z \) to \( v \) leaves \( v \), which is impossible since \( v \in A \). This contradiction yields (iii) and completes the proof of the lemma.

Based on Lemma 5.5, we now finish the proof of Proposition 3.3. Consider \( B_p = \{ \theta_{w^t} \} \) and let \( e_{w^t,s} \) be the unique edge in \([A, B_p]\). Then \([A, B_p] = \{e_{w^t,s} \mid t \in T - \{s\}\} \). Consider the maximum fractional BD-flow \( f \) as before. By the goodness of \( f \) (see (3.2)), we have

\[
\begin{align*}
f[A, B_p] - f[A, B_p] &= f(e_{w^t,s}) - \sum_{t \in T - \{s\}} f(e_{w^t,s}) \\
&= f(e_{w^t,s}) - (2f(e_{w^t,s}) - f(e_{w^t,s})) = 2(f(e_{w^t,s}) - f(e_{w^t,s})) \leq 0 = c[A, B_p] - 1.
\end{align*}
\]

Using this and (5.4), we have

\[
\begin{align*}
\text{val}(f) &= \text{div}_f(z) = \sum_{v \in A} \text{div}_f(v) = 2f[A, A] - 2f[A, A] + \left( f[A] - f[A] \right) \\
&= \left( 2f[A, A] - 2f[A, A] \right) + \left( f[A, M] - f[A, M] \right) + \sum_{p=1}^{k} \left( f[A, B_p] - f[A, B_p] \right) \\
&\leq 2c[A, A] + c[A, M] + \sum_{p=1}^{k} \left( c[A, B_p] - 1 \right) = 2c[A, A] + c[A] - k = c(B) = \text{val}(g).
\end{align*}
\]

Thus, we obtain the desired relation \( \text{val}(f) \leq \text{val}(g) \) (which, in fact, holds with equality). This completes the proof of Proposition 3.3.
6 Dual half-integrality

6.1 Polyhedral approach

Theorem 6.1 Let \( a : VG \to \mathbb{Z}_+ \) and \( p \in \mathbb{Z}_+ \). Then problem \((D_\lambda)\) has a half-integer optimal solution.

Proof. The proof follows easily from Theorem 2.1 and the general fact that the “totally dual 1/k-integrality” implies the “totally primal 1/k-integrality”, which is a natural generalization of a well-known result on TDI systems due to Edmonds and Giles [EG77]. More precisely, we utilize the following simple fact (see, e.g., [Ka89, Statement 1.1]):

Lemma 6.2 Let \( A \) be a nonnegative \( m \times n \)-matrix, \( b \) be an integral \( m \)-vector, and \( k \) be a positive integer. Suppose that the program \( D(c) := \max \{yb \mid y \in \mathbb{Q}_+^m, yA \leq c\} \) has a 1/k-integer optimal solution for every nonnegative integral \( n \)-vector \( c \) such that \( D(c) \) has an optimal solution. Then for every nonnegative integral \( n \)-vector \( c \), the program \( P(c) := \min \{cx \mid x \in \mathbb{Q}_+^n, Ax \geq b\} \) has a 1/k-integer optimal solution whenever it has an optimal solution.

In our case, we set \( k := 2 \) and take as \( A \) (resp. \( b \)) the constraint matrix (resp. the right hand side vector) of \((D_\lambda)\). Then \( b \) is integral, \( D(c) \) becomes \((N_\lambda)\), \( P(c) \) becomes \((D_\lambda)\), and the half-integrality for the former implies that for the latter. \( \square \)

This proof is not “constructive” and does not lead directly to an efficient method for finding a half-integer optimal solution \( l \) to \((D_\lambda)\). Below we devise a strongly polynomial algorithm.

6.2 The algorithm

It gets arbitrary (rational-valued) optimal solutions \( l \) and \( F \) to \((D_\lambda)\) and \((N_\lambda)\), respectively, and outputs a half-integer optimal solution \( \hat{l} \) to \((D_\lambda)\). (Such \( l \) and \( F \) can be found in strongly polynomial time as described in Section 4.)

As before, we set \( \ell := \pi + \bar{l} \), and in what follows, speaking of a geodesic, we always mean an \( \ell \)-geodesic in \( G \), i.e. a \( T \)-path \( P \) with \( \ell(P) = a(P) + l(P) = \lambda \). Our goal is to construct \( \hat{l} : VG \to \frac{1}{2}\mathbb{Z}_+ \) satisfying the following conditions:

\[
\begin{align*}
(i) \quad a(P) + \hat{l}(P) & \geq \lambda \text{ for any } T \text{-path } P \text{ in } G; \\
(ii) \quad a(P) + \hat{l}(P) & = \lambda \text{ for each } T \text{-path } P; \\
(iii) \quad \text{for } v \in VG, \text{ if } l(v) = 0 \text{ then } \hat{l}(v) = 0.
\end{align*}
\]

Then (6.1) and the complementary slackness conditions (2.6)–(2.7) imply that the node lengths \( \hat{l} \) form an optimal solution to \((D_\lambda)\).

We construct an undirected graph \( \Gamma \) and endow it with edge lengths \( \mu : E\Gamma \to \mathbb{Z}_+ \) as follows. We first include in \( \Gamma \) the terminal set \( T \) and all nodes and edges of \( G \) contained in geodesics. Also we add to \( \Gamma \) the edges of \( G \) with both ends lying on geodesics or in \( T \). The edges \( e \) of the current \( \Gamma \) are called regular and we define \( \mu(e) := 0 \).

Next we add to \( \Gamma \) additional edges, which are related to constraints due to parts of \( G \) outside \( \Gamma \). More precisely, we scan all pairs of nodes \( u, v \in VT \) not connected by a
(regular) edge and such that there exists a path $Q$ in $G$ having all nodes in $VG - VΓ$ and whose first node is adjacent to $u$, and the last node to $v$. We add to $Γ$ an edge $e = uv$, referring to it as a virtual edge, and define its length $µ(e)$ to be the minimum value of $a(Q)$ among such paths $Q$. The construction of $Γ, µ$ reduces to a polynomial number of usual shortest paths problems in $G$.

Note that $l(v) = 0$ holds for each node $v ∈ VG - VΓ$ (by (2.6) and (2.7)). We assign $\hat{l}(v) := 0$ for these nodes $v$ and will further focus on finding values of $\hat{l}$ on the nodes in $Γ$.

For a path $P$ in $Γ$, let $Λ(P)$ denote its full length $a(P) + l(P) + µ(P)$. Clearly $Λ(P) ≥ λ$ holds for any $T$-path $P$ in $Γ$, and for each $T$-path $Q$ in $G$, there exists a shortcut path $P$ in $Γ$ such that $Λ(P) ≤ a(Q) + l(Q)$.

The desired lengths $\hat{l}$ on $VT$ will be extracted from a system of linear constraints described below. For a node $v ∈ VT$, let $T_v$ ($Π_v$) denote the set of terminals $s ∈ T$ (resp. pairs $s, t ∈ T$) such that $v$ belongs to a geodesic from $s$ (resp. connecting $s$ and $t$). When a terminal $s$ belongs to no geodesic, we set by definition $T_s := \{s\}$. For each $v ∈ VT$ and $s ∈ T_v$, we introduce two variables $ρ_s^−(v)$ and $ρ_s^+(v)$ and impose the following constraints:

\[ (6.2) \]

(i) For each $s ∈ T$, $ρ_s^−(s) = 0$.

(ii) For each $v ∈ VT$ and $s ∈ T_v$,

\[
ρ_s^+(v) - ρ_s^−(v) = a(v) \quad \text{if } l(v) = 0,
\]

\[
≥ a(v) \quad \text{if } l(v) > 0.
\]

(iii) For each $v ∈ VT$ and $\{s, t\} ∈ Π_v$, $ρ_s^+(v) + ρ_t^−(v) = λ$ (and $ρ_s^+(v) + ρ_s^−(v) = λ$).

(iv) If $e = uv ∈ ET$ and $s ∈ Tu ∩ Tv$, then

\[
ρ_s^−(v) - ρ_s^+(u) ≤ µ(e),
\]

\[
ρ_s^+(u) - ρ_s^+(v) ≤ µ(e).
\]

Moreover, if there exists a geodesic from $s$ containing both $u, v$ in this order (resp. in the order $v, u$), then the former (resp. the latter) inequality is replaced by equality. (Note that in this case $µ(e) = 0$.)

(v) If $e = uv ∈ ET$, $s ∈ Tu, t ∈ Tv$, and $s ≠ t$, then $ρ_s^+(u) + ρ_t^−(v) ≥ λ - µ(e)$.

The meaning of these variables becomes evident from the proof of the next statement.

**Lemma 6.3** System (6.2) has a feasible solution.

**Proof.** For a $p$-$q$ path $P$ in $Γ$, define its pre-length to be $Λ(P) - (a(q) + l(q))$ (i.e. compared with the full length, we do not count the last node). For $v ∈ VT$ and $s ∈ T_v$, define $ρ_s^−(v)$ (resp. $ρ_s^+(v)$) to be the minimum pre-length (resp. minimum full length) of an $s$-$v$ path in $Γ$. Then (6.2)(i)–(iii) follow from the construction. Condition (6.2)(iv) represents a sort of triangle inequalities (giving one equality if $e$ belongs to a geodesic from $s$). Finally, condition (6.2)(v) holds since the full length of any $s$-$t$ path in $Γ$ is at least $λ$.

We observe that in linear system (6.2), each constraint contains at most two variables, each occurring with the coefficient 1 or −1, and that the right-hand side in it is an integer.
A well-known fact is that a linear system with such features is totally dual half-integral; therefore, it has a half-integer basis solution (whenever it has a solution at all), and such a solution can be found in strongly polynomial time (cf., e.g., [EJ70, Sc03]).

Given a half-integer solution $(\rho^-, \rho^+)$ to (6.2), we define half-integer node lengths $\hat{l}$ as follows:

$$\hat{l}(v) := \rho^+_s(v) - \rho^-_s(v) - a(v) \quad \text{for all } v \in VT \text{ and } s \in T_v.$$  

Now the desired algorithmic result is provided by the following

**Lemma 6.4** $\hat{l}$ is well-defined and satisfies (6.1).

**Proof.** We first show that for any $v \in VT$ and $s, t \in T_v$,

$$\rho^+_s(v) - \rho^-_s(v) = \rho^+_t(v) - \rho^-_t(v).$$  

This is trivial when $\Pi_v = \emptyset$ (since in this case $v \in T$ and $T_v = \{v\}$). Let $\Pi_v \neq \emptyset$. If $\{s, t\} \in \Pi_v$, then (6.3) follows from (6.2)(iii). Now (6.3) with any two $s, t \in T_v$ is implied by the fact that the graph whose nodes and edges are the elements of $T_v$ and $\Pi_v$, respectively, is connected (as it is easy to see that for $\{s, t\}, \{p, q\} \in \Pi_v$, at least one of $\{s, p\}, \{s, q\}$ is in $\Pi_v$ as well). So $\hat{l}$ is well-defined.

Property (6.1)(iii) is immediate from (6.2)(ii).

To see (6.1)(ii), consider an $s$–$t$ geodesic $P$. Going along $P$ step by step and applying (6.2)(ii),(iv), we observe that for each node $v$ on $P$, the $s$–$v$ part $P'$ of $P$ satisfies $a(P') + l(P') = \rho^+_s(v) - \rho^-_s(s)$. When reaching $t$, we obtain $a(P) + l(P) = \rho^+_t(t) - \rho^-_s(s)$, and now (6.1)(ii) follows from (6.2)(iii) and $\rho^-_s(s) = \rho^-_t(t) = 0$ (by (6.2)(i))

Finally, consider an arbitrary $T$-path $Q$ in $\Gamma$, from $p$ to $q$ say. To conclude with (6.1)(i), it suffices to show that

$$\Delta(Q) := a(Q) + \hat{l}(Q) + \mu(Q) \geq \lambda.$$  

Represent $Q$ as the concatenation $Q' \cdot Q''$, where $Q'$ is a part of a geodesic from $p$. We prove (6.4) by induction on the number $|Q''|$ of edges in $Q''$. When $|Q''| = 0$, $Q$ is a geodesic, and we are done. Assuming this is not the case, take the first edge $e = uv$ of $Q''$, where $u$ is the end of $Q'$. By reasonings above, $\Delta(Q') = \rho^+_p(u)$. If $v \in T$ (and therefore, $v = q$), (6.4) immediately follows from (6.2)(v) with $s := q$ and $t := q$. And if $v \notin T$, then $v$ belongs to some $s$–$t$ geodesic $L$. W.l.o.g., one may assume that $s \neq p$ and $t \neq q$. Applying (6.2)(v) to $s, p, e$, we have

$$\rho^+_p(u) + \rho^+_s(v) + \mu(e) \geq \lambda.$$  

Comparing this with $\rho^-_s(v) + \rho^+_t(v) = \lambda$ and using $\rho^+_s(v) - \rho^-_s(v) = a(v) + \hat{l}(v)$, one can conclude that $\Delta(Q) \geq \Delta(R)$, where $R$ is the $t$–$q$ path being the concatenation of the $t$–$v$ part of (the reverse of) $L$ and the $v$–$q$ part $R''$ of $Q$. Since $|R''| = |Q''| - 1$, we can apply induction and obtain $\Delta(Q) \geq \Delta(R) \geq \lambda$, as required.  

□
Appendix: Skew-symmetric graphs and flows

In this section we recall the notions of skew-symmetric graphs and integer skew-symmetric flows, review known results on such graphs and flows, and then use them to derive necessary results on bidirected graphs and flows to which we appealed in Section 5.

7.1 Skew-symmetric graphs

A skew-symmetric graph, or an SK-graph for short, is a digraph $G = (V G, A G)$, with possible parallel arcs, endowed with two bijections $\sigma_V, \sigma_A$ such that: $\sigma_V$ is an involution on the nodes (i.e. $\sigma_V(v) \neq v$ and $\sigma_V(\sigma_V(v)) = v$ for each node $v$); $\sigma_A$ is an involution on the arcs; and for each arc $a$ from $u$ to $v$, $\sigma_A(a)$ is an arc from $\sigma_V(v)$ to $\sigma_V(u)$. For relevant results on SK-graphs and a relationship between SK- and BD-graphs, see [Tu67, GK96, GK04, BK07]. For brevity $\sigma_V$ and $\sigma_A$ are combined into one mapping $\sigma$ on $V G \cup A G$, which is called the symmetry (or skew-symmetry, to be precise) of $G$.

For a node (arc) $x$, its symmetric node (arc) $\sigma(x)$ is also called the mate of $x$, and we usually use notation with primes for mates, denoting $\sigma(x)$ by $x'$. Although $G$ is allowed to contain parallel arcs, when it is not confusing, an arc from $u$ to $v$ may be denoted as $(u,v)$.

Observe that if $G$ contains an arc $a$ from a node $v$ to its mate $v'$, then $a'$ is also an arc from $v$ to $v'$ (i.e. $a'$ is parallel to $a$).

The symmetry $\sigma$ is extended in a natural way to walks, subgraphs and other objects in $G$. In particular, two walks are symmetric to each other if the elements of one of them are symmetric to those of the other and go in the reverse order: for a walk $P = (v_0, a_1, v_1, \ldots, a_k, v_k)$, the symmetric walk $P' = \sigma(P)$ is $(v_k', a_k', v_{k-1}', \ldots, a_1', v_0')$.

Next we explain a relationship between skew-symmetric and bidirected graphs. Given an SK-graph $G$, choose an arbitrary partition $\pi = (V_1, V_2)$ of $V G$ such that $V_2 = \sigma(V_1)$. Then $G$ and $\pi$ determine the BD-graph $G^\ast$ with $V G^\ast = V_1$ whose edges correspond to the pairs of symmetric arcs in $G$. More precisely, arc mates $a, a'$ of $G$ generate one edge $e$ of $G^\ast$ connecting nodes $u, v \in V_1$ such that: (i) $e$ goes from $u$ to $v$ if one of $a, a'$ goes from $u$ to $v$ (and the other goes from $v$ to $u'$ in $V_2$); (ii) $e$ leaves both $u, v$ if one of $a, a'$ goes from $u$ to $v'$ (and the other from $v$ to $u'$); (iii) $e$ enters both $u, v$ if one of $a, a'$ goes from $u'$ to $v$ (and the other from $v'$ to $u$). Note that $e$ becomes a loop if $a, a'$ connect a pair of symmetric nodes.

Conversely, a BD-graph $G^\ast$ determines an SK-graph $G$ with symmetry $\sigma$ as follows. Make a copy $\sigma(v)$ of each element $v$ of $V^\ast := V G^\ast$, forming the set $(V^\ast)' := \{\sigma(v) \mid v \in V^\ast\}$. Put $V G := V^\ast \sqcup (V^\ast)'$. For each edge $e$ of $G^\ast$ connecting nodes $u$ and $v$, assign two "symmetric" arcs $a, a'$ in $G$ so as to satisfy (i)-(iii) above (where $u' = \sigma(u)$ and $v' = \sigma(v)$). An example is depicted in Fig. 3.

**Remark 7.1** Note that one BD-graph generates one SK-graph, by the second construction. On the other hand, one SK-graph generates a set of BD-graphs, depending on the partition $\pi$ of $V G$, by the first construction. Namely, for each pair of symmetric mates $(v, v')$ in $G$ one may distribute $v, v'$ between $V_1, V_2$ so that either $v \in V_1, v' \in V_2$ or, reversely, $v \in V_2, v' \in V_1$. The resulting BD-graphs are obtained from one other by making corresponding flips (defined in Subsection 5.1).
There is essentially a one-to-one correspondence between the walks in $G^*$ and $G$. More precisely, let $\tau$ be the natural mapping of $VG \cup AG$ to $VG^* \cup EG^*$. Each walk $P = (v_0, a_1, v_1, \ldots, a_k, v_k)$ in $G$ (where $a_i = (v_{i-1}, v_i)$) induces the sequence

$$\tau(P) := (\tau(v_0), \tau(a_1), \tau(v_1), \ldots, \tau(a_k), \tau(v_k))$$

of nodes and edges in $G^*$. One can see that $\tau(P)$ is a walk in $G^*$ (i.e. $\tau(a_i), \tau(a_{i+1})$ form a transit pair at $\tau(v_i)$, for each $i$) and that $\tau(P')$ is the walk reverse to $\tau(P)$. Moreover, for any walk $P^*$ in $G^*$, there is exactly one walk $P$ in $G$ such that $\tau(P) = P^*$ (considering $P$ up to replacing an arc $a \in AP$ by its mate $a'$ when $a, a'$ are parallel, i.e. correspond to a loop in $G^*$).

### 7.2 Skew-symmetric flows

We call a function $\varphi$ on the arcs of an SK-graph $G$ (self-)symmetric if $\varphi(a) = \varphi(a')$ for all $a \in AG$. Let $s \in VG$ be a designated source; its mate $s'$ is regarded as the sink.

An integer skew-symmetric $s-s'$ flow, or an ISK-flow for short, is a symmetric function $f : AG \rightarrow \mathbb{Z}_+$ being an $s-s'$ flow in a usual sense: $\text{div}_f(v) = 0$ for all $v \in VG - \{s, s'\}$, and $\text{div}_f(s) \geq 0$. The value of $f$ is $\text{val}(f) := \text{div}_f(s)$. Here $\text{div}_f(v)$ denotes the usual divergence (given by (3.1), where $\delta^\text{in}(v)$ and $\delta^\text{out}(v)$ are the sets of arcs entering and leaving $v$, respectively).

For a capacity function $c : AG \rightarrow \mathbb{Z}_+$, a flow $f$ is said to be feasible if $f(a) \leq c(a)$ for all $a \in AG$. We refer to a feasible ISK-flow of maximum possible value as a maximum ISK-flow.

The above correspondence between BD- and SK-graphs is naturally extended to flows. More precisely, if $f$ is a symmetric $s-s'$ flow in $G$, then transferring the values of $f$ from the pairs of arc mates of $G$ to the edges of the corresponding BD-graph $G^*$, we obtain a $\tau(s)$-flow in $G^*$, denoted as $f^*$. The converse correspondence is evident as well.

For $X, Y \subseteq VG$, let $(X, Y)$ denote the set of arcs going from $X$ to $Y$. Also (accommodating notation from Section 5 to digraphs) we denote by $[\overline{X}]$ the set of arcs leaving $X$. 

Figure 3: Related bidirected and skew-symmetric graphs.
Let \( c : AG \to \mathbb{Z}_+ \) be a symmetric capacity function. Then a tuple \( \mathcal{B} = (A, M; B_1, \ldots, B_k) \) of subsets of \( VG \) is called a (skew-symmetric) odd barrier (w.r.t. the source \( s \)) if the following conditions hold (see Fig. 4):

\[
\begin{align*}
(7.1) & \quad \text{(i) the sets } A, A', M, B_1, \ldots, B_k \text{ give a partition of } VG, \text{ each } B_i \text{ is self-symmetric } (B_i' = B_i), \text{ and } s \in A; \\
& \quad \text{(ii) For each } i = 1, \ldots, k, \ c(A, B_i) \text{ is odd.} \\
& \quad \text{(iii) For distinct } i, j = 1, \ldots, k, \ c(B_i, B_j) = 0. \\
& \quad \text{(iv) For each } i = 1, \ldots, k, \ c(B_i, M) = c(M, B_i) = 0.
\end{align*}
\]

The capacity of \( \mathcal{B} \) is defined to be

\[
(7.2) \quad c(\mathcal{B}) := c(\overline{A}) - k.
\]

Odd barriers in skew-symmetric graphs are related to their bidirected counterparts introduced in Section 5. Indeed, consider a BD-graph \( G^* \) with integer edge capacities \( c : E G^* \to \mathbb{Z}_+ \) and a source \( s \). Construct the related SK-graph \( G \) with \( VG = V \cup V' \), where \( V := VG^* \). Edge capacities \( c \) in \( G^* \) induce symmetric arc capacities in \( G \), also denoted by \( c \). The source \( s \) in \( G^* \) gives the source \( s \) and the sink \( s' \) in \( G \). Consider a skew-symmetric odd barrier \( \mathcal{B} = (A, M; B_1, \ldots, B_k) \) in \( G \).

This barrier gives rise to the following odd BD-barrier \( B^* \) in \( G^* \) obeying \( c(B^*) = c(\mathcal{B}) \). We first construct a new BD-graph from \( G \) by taking a bipartition \( (V_1, V_2 = \sigma(V_1)) \) of \( VG \) such that \( A \subseteq V_1 \) and \( V_1 - (A \cup A') = V - (A \cup A') \); cf. Remark 7.1. The resulting BD-graph \( H^* \) is equivalent to \( G^* \). Moreover, \( H^* \) is obtained from \( G^* \) by flipping a subset of nodes within \( A \).

The node subsets \( M, B_1, \ldots, B_k \) in \( G \) are self-symmetric and induce subsets \( M^*, B^*_1, \ldots, B^*_k \) in \( G^* \) and \( H^* \) in a natural way; namely, \( M^* := M \cap V = M \cap V_1 \) and similarly for \( B^*_i \). Define \( B^* := (H^*[A^*, M^*; B^*_1, \ldots, B^*_k]), \) where \( A^* := (A \cup A') \cap V_1 \).

A straightforward examination shows that the properties in (7.1) imply their bidirected counterparts in (5.1). To see that \( c(B^*) = c(\mathcal{B}) \), define \( Z := M \cup B_1 \cup \ldots \cup B_k \). Note that \( c[A] = c(A, A') + c(A, Z) \). The capacity \( c(A, A') \) is equal to \( 2c[A^*, A^*] \) (in \( H^* \) since
(A, A') consists of pairs of arc mates, each pair corresponding to an edge in \( \overrightarrow{A} \). And the capacity \( c(A, Z) \) is equal to \( c[\overrightarrow{A}] \) since the (symmetric) set \( Z \) corresponds to \( M^* \cup B_1^* \ldots B_k^* \) in \( H^* \).

In light of these observations, Theorem 5.1 is a consequence of the following Tutte's theorem. (For shorter proofs of this and next theorems, see also [GK04],)

**Theorem 7.2** (Max ISK-Flow Min Odd Barrier Theorem [Tu67]) For \( G, c, s \) as above, the maximum ISK-flow value is equal to the minimum odd barrier capacity. An ISK-flow \( f \) and an odd barrier \( B = (A, M; B_1, \ldots, B_k) \) have maximum value and minimum capacity, respectively, if and only if the following hold:

(i) \( f(A, A' \cup M) = c(A, A' \cup M) \) and \( f(A' \cup M, A) = 0 \);

(ii) for each \( i = 1, \ldots, k \), either \( f(A, B_i) = c(A, B_i) - 1 \) and \( f(B_i, A) = 0 \), or \( f(A, B_i) = c(A, B_i) \) and \( f(B_i, A) = 1 \).

Next we establish additional correspondences. Consider an ISK-flow \( f \) in \( G \). The residual SK-graph \( G_f \) endowed with the residual capacities \( c_f : AG_f \to \mathbb{Z}_+ \) is constructed in a standard fashion: \( VG_f = VG \), and the arcs of \( G_f \) are:

\[
\text{(7.3)} \quad (i) \text{ each arc } a \in AG \text{ with } f(a) < c(a) \text{ whose residual capacity is defined to be } c_f(a) := c(a) - f(a), \text{ and }
\]

(ii) the reverse arc \( a^R = (v, u) \) to each arc \( a = (u, v) \in AG \) with \( f(a) > 0 \); its residual capacity is \( c_f(a^R) := f(a) \)

(cf. (5.3)). A path \( P \) in \( G_f \) is called \( c_f \)-regular if \( c_f(a) = c_f(a') \geq 2 \) holds for each pair of arc mates \( a, a' \) occurring in \( P \). (In other words, the bidirected image of \( P \) in \( G_f^* \) is a \( c_f \)-simple walk.) If \( P \) is a \( c_f \)-regular \( s-s' \) path, we can increase the value of \( f \) by 2 (by sending one unit of flow along \( P \) and one unit of flow along \( P' \)). So the existence of such a \( P \) implies the non-maximality of \( f \). The converse property is valid as well.

**Theorem 7.3** ([Tu67]) An ISK-flow \( f \) is maximum if and only if there is no \( c_f \)-regular \( s-s' \) path in \( G_f \).

This implies Theorem 5.2 for IBD-flows.

Given a maximum ISK-flow \( f \), a certain minimum odd barrier can be constructed by considering the residual graph \( G_f \). The construction described in the proof of Theorem 3.5 in [GK04] (relying on Lemma 2.2 in [GK96]) is as follows.

**Theorem 7.4** Let \( f \) be a maximum ISK-flow. Let \( R = R_f \) be the set of nodes reachable from \( s \) by \( c_f \)-regular paths in \( G_f \). Define \( A := R - R' \) and \( M := VG - (R \cup R') \). Let \( B_1, \ldots, B_k \) be the node sets of weakly connected components of the subgraph \( G \) induced by \( R \cap R' \). Then \( B_f := (A, M; B_1, \ldots, B_k) \) is a minimum odd barrier.

This subset \( R \) of nodes in \( G \) corresponds to two sets \( \overrightarrow{R} = \overrightarrow{R}_{G^*, f} \) and \( \overrightarrow{R} = \overrightarrow{R}_{G^*, f} \) in \( G^* \) (defined just before Theorem 5.3; here \( \Gamma = G^* \) and \( g = f^* \)). More precisely, assuming that each node \( v \in VG^* \) corresponds to node mates \( v, v' \) in \( G \) (cf. Subsection 7.1), one can realize that \( \overrightarrow{R} \) (resp. \( \overrightarrow{R} \)) is the set of nodes \( v \in VG^* \) such that \( v \in R \) (resp. \( v' \in R \)).

Finally, the last theorem in Subsection 5.1 (Theorem 5.4) is implied by the following assertion.
Theorem 7.5 The sets $R_f$ in Theorem 7.4 are equal for all maximum ISK-flows $f$. Therefore, the minimum odd barriers $B_f$ are equal as well.

This fact can be extracted from reasonings in [GK04], yet it is not formulated there explicitly. For this reason, we give a direct proof.

Let $f$ be a maximum ISK-flow such that the set $R_f$ is inclusion-wise minimal and let $B_f := (A, M; B_1, \ldots, B_k)$. Consider another maximum ISK-flow $g$ (if any). Then

\begin{equation}
(7.4) \quad c[A] - k = c(B) = \text{val}(g) = \sum_{v \in A} \text{div}_g(v)
\end{equation}

where for disjoint subsets $X, Y \subset VG$, $g(X, Y)$ denotes $g(X, Y) - g(Y, X)$. For $i = 1, \ldots, k$, we have: $g(A, B_i) \leq c(A, B_i)$; $c(A, B_i)$ is odd; and $g(A, B_i)$ is even (the latter is due to a result in [Tu67]; see also [GK04, Corollary 3.2]). Therefore, $c(A, B_i) - g(A, B_i) \geq 1$. Also $g(A, A') \leq c(A, A')$ and $g(A, M) \leq c(A, M)$. Comparing these relations with (7.4), we conclude that:

(i) all arcs in $(A, A' \cup M)$ are saturated by $g$, while all arcs $a$ in $(A' \cup M, A)$ are free of $g$ (i.e. $g(a) = 0$);
(ii) for each $i$, $g(A, B_i) = c(A, B_i) - 1$.

In terms of the residual graph $G_g$, (i) and (ii) mean that the sets $A$ and $VG - A$ are connected in $G_g$ by exactly $k$ arcs $a_1, \ldots, a_k$, each $a_i$ going from $A$ to $B_i$ and having the residual capacity 1. By symmetry, $VG - A'$ and $A'$ are connected by only the arcs $a'_1, \ldots, a'_k$ (each $a'_i$ goes from $B_i$ to $A'$, and $c_g(a_i) = c_g(a'_i) = 1$). Also by (7.1)(iii),(iv), no arc in $G_g$ connects different sets among $M, B_1, \ldots, B_k$. Therefore, the set $R_g$ of nodes in $G_g$ reachable from $s$ by $c_g$-regular paths is contained in $R_f$. By the minimality of $R_f$, we have $R_f = R_g$, as required. \hfill \Box
